

A Self-Catalyzing Hydrogen-Storage Material**

Jun Yang,* Andrea Sudik, Donald J. Siegel, Devin Halliday, Andrew Drews, Roscoe O. Carter III, Christopher Wolverton, Gregory J. Lewis, J. W. Adriaan Sachtler, John J. Low, Syed A. Faheem, David A. Lesch, and Vidvuds Ozolinš

Conventional (e.g. MgH_2) and complex hydrides (e.g. alanes, borohydrides, and amides) are the two primary classes of solid-state hydrogen-storage materials.^[1-3] Many of these “high-density” hydrides have the potential to store large amounts of hydrogen by weight (up to 18.5 wt% for LiBH_4) and/or volume (up to 112 g L^{-1} for MgH_2), values that are comparable to the hydrogen content of gasoline (15.8 wt%, 112 g L^{-1}). However, all known hydrides are inadequate for mobile storage applications due to one or more of the following limitations: a) unfavorable thermodynamics (they require high temperatures to release hydrogen^[4]), b) poor kinetics (low rates of hydrogen release and uptake), c) decomposition pathways involving the release of undesirable by-products (e.g. ammonia), and/or d) an inability to reabsorb hydrogen at modest temperatures and pressures (i.e. “irreversibility”).

In spite of these drawbacks, renewed interest in complex hydrides has been stimulated recently by substantial improvements in their kinetics and reversibility^[5,6] provided by catalytic doping (e.g. TiCl_3 -doped NaAlH_4),^[7,8] and by thermodynamic enhancements achieved through reactive binary mixtures^[9] such as $\text{LiNH}_2/\text{MgH}_2$,^[10,11] $\text{LiBH}_4/\text{MgH}_2$,^[12] and $\text{LiNH}_2/\text{LiBH}_4$.^[13,14] These compositions, previously termed “reactive hydride composites”,^[15] represent the state-of-the-art in hydrogen-storage materials; compared to their constituent compounds, they exhibit improved thermodynamic properties, higher hydrogen purity, and, in some cases, reversibility. The desorption behavior of these previ-

ously studied composites is illustrated in Figure 1a. It is evident from the hydrogen desorption profile (top panel) that the composites generally desorb hydrogen at significantly lower temperatures than their individual components. For example, the lowest temperature reaction, which involves a

Figure 1. a) Hydrogen (top) and ammonia (bottom) kinetic desorption data as a function of temperature (5 °C min^{-1} to 550 °C) for the ternary composition (blue trace) and its unary and binary constituents. Hydrogen desorption is measured in weight percent (wt%) to 1 bar whereas relative ammonia release is measured as partial pressure (torr) in a flow-through set-up (100 sccm Ar). b) Ternary phase space defined by unary compounds (nodes), LiBH_4 (pink), MgH_2 (purple), and LiNH_2 (orange) and the binary mixtures (edges), $\text{LiBH}_4/\text{MgH}_2$ (gray), $\text{MgH}_2/\text{LiNH}_2$ (green), and $\text{LiNH}_2/\text{LiBH}_4$ (red). The present ternary composition, which is a 2:1:1 mixture of LiNH_2 , LiBH_4 , and MgH_2 , and previously investigated binaries, are identified.

Supporting information for this article is available on the WWW under <http://www.angewandte.org> or from the authors.

2:1 mixture of LiNH_2 and MgH_2 , has a desorption temperature more than 100°C lower than that of either MgH_2 (approx. 350°C) or LiNH_2 (which releases only NH_3) alone. Although these binary reactions present significant benefits, they all have well-known disadvantages: a) their lowered desorption temperatures are still too high, b) the reaction involving LiNH_2 and LiBH_4 is irreversible, c) the nitrogen-containing binaries $\text{LiNH}_2/\text{MgH}_2$ and $\text{LiNH}_2/\text{LiBH}_4$ emit a significant amount of ammonia (a proton-exchange membrane fuel cell (PEM-FC) poison) together with the hydrogen (Figure 1 a, bottom panel), and, most significantly, d) hydrogen desorption/uptake in *all* of these binary composites is too slow. Therefore, further improvement in these areas is highly desirable.

Herein we present a strategy for enhancing the properties of binary composites through the creation of a multi-component composite of three hydride compounds ($2\text{LiNH}_2/\text{LiBH}_4/\text{MgH}_2$). The improved properties of this system arise almost entirely from a “self-catalyzing” reaction pathway that results in faster kinetics and lower desorption temperatures than for the binary composites and almost complete suppression of ammonia release. The key elements that contribute to the enhanced properties are the incorporation of a low melting temperature ionic liquid ($\text{Li}_4\text{BH}_3\text{H}_{10}$) and a mechanism for seeding the products of a reversible hydrogen desorption reaction.^[16]

The choice of the $2\text{LiNH}_2/\text{LiBH}_4/\text{MgH}_2$ stoichiometry is based on several factors: a) the constituent hydrides all possess high gravimetric/volumetric capacities, b) binary mixtures of these hydrides are among the best known hydrogen-storage materials (see Figure 1 a, top panel), c) mixtures containing MgH_2 are known to suppress ammonia release from nitrogen-containing hydrides such as LiNH_2 (Figure 1 a, bottom panel), and d) a stable, lightweight compound, namely lithium magnesium boron nitride (LiMgBN_2), which contains N, B, and Mg in a 2:1:1 ratio (the same as our stoichiometric composite), is known which could serve as a potential dehydrogenated product phase. The compositional phase space of the ternary composite is shown in the Gibbs triangle in Figure 1 b and information regarding the sample synthesis and preparation conditions is given in the Experimental Section.

We begin our discussion of this system by summarizing its principal hydrogen-storage attributes in relation to those of the unary and binary components. Employing a wide range of experimental phase analyses and first-principles evaluation of reaction thermodynamics, we subsequently identify a complex, “cascading” sequence of reactions that explain the observed properties. We conclude with a more detailed discussion of the proposed “self-catalyzing” mechanism.

Lowered desorption temperatures: The measured kinetic desorption behavior (5°C min^{-1} , 1 bar) of the ternary composite is compared with the constituent unary and binary components in the upper panel of Figure 1 a. The ternary system rapidly releases hydrogen in a process that begins at 150°C (top panel), which is about $50\text{--}200^\circ\text{C}$ lower than the binary composites, thereby indicating significantly improved kinetics and/or thermodynamics. The total capacity of the ternary composite is $8.2\text{ wt}\%$.

Improved hydrogen purity: The composition of the gas released from the ternary composite while heating at 5°C min^{-1} in a flow of 100 sccm argon is plotted in comparison with the binary composites in the lower panel of Figure 1 a. The ammonia released by the ternary composite is less than the 100 ppm detection limit of our instrument; the ammonia released from the nitrogen-containing binaries was found to be more than an order of magnitude larger. No other volatile boron- and/or nitrogen-containing by-products were detected throughout the desorption process.

Reversibility: The reversible storage capacity and response to cycling were determined from a series of charge/discharge experiments performed with a Sievert-type PCT apparatus at 160°C and charging (discharging) at 100 (1) bar . The results for five charge/discharge cycles (Figure 2 a) show that the as-prepared material rapidly releases approximately $3.0\text{ wt}\%$ of hydrogen within 20 minutes. After recharging, the second through fifth

Figure 2. a) Hydrogen desorption kinetics at 160°C and 1 bar over five cycles after subsequent charging (160°C and 100 bar hydrogen). b) Reversible isothermal kinetic hydrogen desorption data (to 1 bar) for the ternary composition based on the second desorption cycle at 140°C (\bullet), 150°C (\blacktriangledown), 160°C (\square), and 180°C (\blacklozenge) versus time.

desorption cycles consistently liberate around 2.8 wt % of hydrogen, a reversible capacity at moderate temperature that is among the best for solid-state hydrogen storage.^[5–8]

Kinetics: The reversible isothermal kinetic desorption profiles for the second desorption cycle (to 1 bar) were collected at 140, 150, 160, and 180 °C (Figure 2b). The ternary composite is capable of desorbing more than 2.5 wt % hydrogen in times ranging from 10 min (180 °C) to 2.5 h (140 °C) in this temperature range. The remaining hydrogen is liberated in a second step at higher temperatures for a total hydrogen capacity of 8.2 wt % (Figure 3). The initial release of hydrogen at both 260 and 320 °C is dramatically accelerated, with 3.2 wt % released within minutes, while the subsequent desorption steps are more influenced by temperature, reaching full desorption after 1.5 and 14 h at 320 and 260 °C, respectively.

Figure 3. Isothermal kinetic hydrogen desorption to 1 bar for the ternary composition at 260 and 320 °C versus time.

The unique desorption behavior described above strongly suggests that the reaction mechanism(s) of the ternary composite is not a simple superposition of the known binary reactions. To understand its hydrogen-release characteristics, we therefore collected temperature-programmed-desorption mass spectrometry (TPD-MS) data at a constant heating rate and carrier gas flow (5 °C min⁻¹, 100 sccm argon flow; Figure 4a). Four distinct hydrogen-release events occur (maxima at 180, 190 (shoulder), 310, and 560 °C, respectively), with an initial desorption onset at 110 °C.^[17] TPD-MS data were also collected for the cycled/recharged material (See Supporting Information). These data clearly show that the first steep desorption step (at 180 °C) in the as-prepared sample is no longer observed in the recharged sample. Instead, the peak temperature for the recharged sample is now shifted to the shoulder region for the fresh material (approx. 190 °C), thus indicating that the reaction corresponding to the shoulder is reversible, which is consistent with the

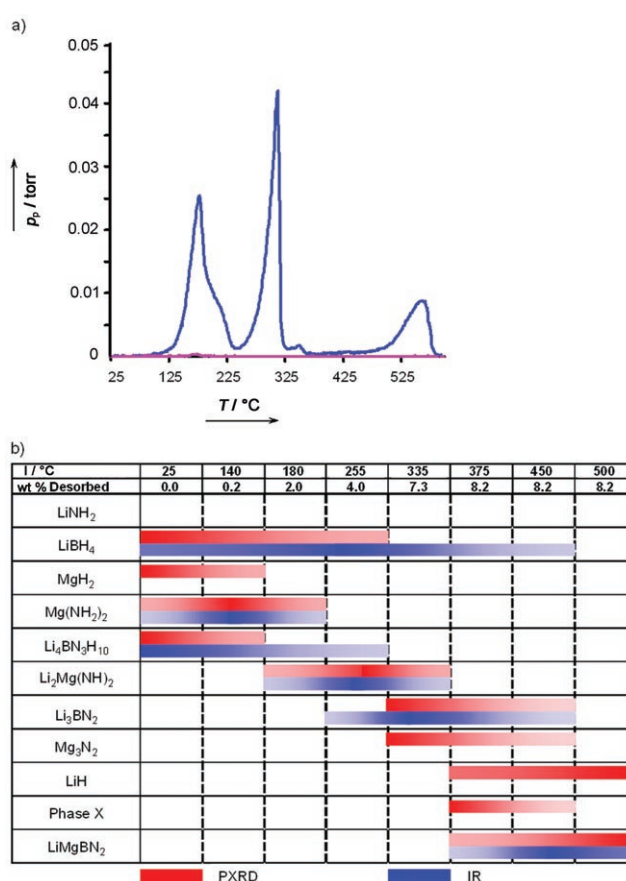

Figure 4. a) TPD-MS data for the ternary composition depicting hydrogen (m/z 2, blue) and ammonia (m/z 17, pink) as a function of temperature (heating at 5 °C min⁻¹ to 575 °C). b) Phase composition as a function of desorbed hydrogen amount (wt %) and temperature (°C) as determined from the static PXR and IR data.

powder X-ray diffraction (PXR) and IR spectroscopic analyses (discussed below).

Phase identification: Phase-composition studies were carried out for identically prepared samples, which were desorbed to varying degrees at 1 bar hydrogen by heating at 5 °C min⁻¹ in a water displacement apparatus (see Supporting Information) to identify the species involved in the various desorption reactions. Following desorption, each sample was quenched and analyzed by PXR and IR spectroscopy. The results are summarized in Figure 4b, and raw data and phase assignments are provided as Supporting Information. The as-prepared sample (ball milling 2 g of LiNH₂, LiBH₄, and MgH₂ in a 2:1:1 ratio for 5 h) contains two new species (Mg(NH₂)₂ and Li₄BN₃H₁₀) and no residual LiNH₂, which is indicative of milling-induced transformations. Residual MgH₂ and LiBH₄ starting materials are also present. Growth of Mg(NH₂)₂ and (weakly crystalline) LiH is detected upon initial heating to 140 °C before any appreciable amount of hydrogen is released. At the same time, the diffraction peaks for Li₄BN₃H₁₀ disappear. As the characteristic symmetric and asymmetric amide N–H IR frequencies (observed: 3301 and 3242 cm⁻¹; literature:^[18] 3303 and 3243 cm⁻¹) persist, we conclude that Li₄BN₃H₁₀ has melted. Further heating to 180 °C results in the release of 2.0 wt % hydrogen (first low

temperature event in Figure 4a) and the formation of $\text{Li}_2\text{Mg}(\text{NH})_2$, based on its three characteristic peaks at 30.7° , 51.3° , and 60.9° in the PXRD pattern^[19] and the signature N–H stretch in the IR spectrum (observed: 3178 cm^{-1} ; literature:^[20] 3187 cm^{-1}). This phase continues to grow in intensity until 255°C , at which point 4.0 wt % H_2 has desorbed. At this stage, MgH_2 and $\text{Mg}(\text{NH}_2)_2$ have been completely consumed while $\text{Li}_4\text{BN}_3\text{H}_{10}$ is significantly depleted.

The second major hydrogen releasing event occurs between 255 and 375°C and corresponds to a total of 8.2 wt % desorbed hydrogen. $\text{Li}_2\text{Mg}(\text{NH})_2$ and LiBH_4 are consumed during this stage and Mg_3N_2 and Li_3BN_2 are formed. Trace amounts of LiH and an unknown phase (denoted as “Phase X”) are also detected by PXRD.^[21] Further heating to 500°C does not produce additional hydrogen but rather an observed phase transformation consistent with the consumption of Li_3BN_2 , Mg_3N_2 , and LiBH_4 and the production of LiH and LiMgBN_2 .^[22] The final hydrogen releasing step ($> 500^\circ\text{C}$) is attributed to decomposition of LiH (third major event in Figure 4a).

Variable-temperature in situ PXRD was used to validate the above phase assignments and to provide phase transformation information (see the Supporting Information for instrument set-up and data collection protocol). Figure 5a shows the raw PXRD data as a function of temperature (25 – 450°C) and Figure 5b shows the two-dimensional contour plot. The phase assemblage as a function of temperature is shown in Figure 5c. The data reveal that the sequence and relative phase contributions are identical to those observed by static PXRD, thereby confirming the proposed reaction sequence. Furthermore, the in situ data reveal that the $\text{Li}_4\text{BN}_3\text{H}_{10}$ and MgH_2 phases disappear rapidly (by 100 and 150°C , respectively) during initial heating of the as-prepared material and prior to any hydrogen release. The observed melting of $\text{Li}_4\text{BN}_3\text{H}_{10}$ at 100°C occurs at a significantly lower temperature than previously reported (150°C).^[23] This low temperature melt may serve as an effective mass transfer medium or homogenizing agent and aid in the distribution of $\text{Li}_2\text{Mg}(\text{NH})_2$ (produced in the first desorption step reaction between $\text{Li}_4\text{BN}_3\text{H}_{10}$ and MgH_2), which would in turn serve as $\text{Li}_2\text{Mg}(\text{NH})_2$ nucleation seeds for a second step reaction

between $\text{Mg}(\text{NH}_2)_2$ and LiH . The presence of the ionic liquid may therefore positively influence the desorption kinetics of the initial hydrogen release reactions.

Reaction pathway: A set of proposed reactions are summarized in Figure 6. Our assignment of reactions takes into account the observed and theoretical hydrogen capacity for each step, the reversible amount of stored hydrogen, and the phase compositions (obtained from both quenched/static and in situ PXRD and IR spectroscopy). A reaction scheme flowchart is included in the Supporting Information. The TPD-MS curve from Figure 4a is incorporated to indicate the temperature region under which each reaction occurs. The reaction enthalpies (ΔH_{calcd}) and free energies (ΔG_{calcd}) at 300 K obtained by density functional theory calculations are also included in this table. The fact that all the calculated free energies are negative suggests that the proposed reactions are thermodynamically reasonable. (The activation energies for reactions (2) and (4) are given as Supporting Information.)

During sample preparation, the starting materials LiNH_2 and LiBH_4 react to form $\text{Li}_4\text{BN}_3\text{H}_{10}$.^[13] Partial reaction of this quaternary phase with a portion of MgH_2 then yields a small amount of $\text{Mg}(\text{NH}_2)_2$. As both reactions are exothermic (based on DFT calculations), it is likely that they occur under ball milling or upon moderate heating. After milling, the phases present include $\text{Li}_4\text{BN}_3\text{H}_{10}$, LiBH_4 , MgH_2 , $\text{Mg}(\text{NH}_2)_2$, and LiH . Upon subsequent heating, but before the onset of hydrogen release, production of $\text{Mg}(\text{NH}_2)_2$ continues according to reaction (1).

Self-catalyzing mechanism: As the temperature reaches 100°C , $\text{Li}_4\text{BN}_3\text{H}_{10}$ melts and reacts with MgH_2 to form $\text{Li}_2\text{Mg}(\text{NH})_2$ and LiBH_4 and releases H_2 at the first low temperature desorption peak [reaction (2)]. This reaction only occurs during desorption of the as-prepared material and not in subsequent cycles (see Supporting Information). More importantly, reaction (2) serves to directly catalyze the subsequent reversible reaction between $\text{Mg}(\text{NH}_2)_2$ and LiH that occurs at the shoulder region (approx. 190 – 230°C) [reaction (3)].

A Self-Catalyzing Hydrogen-Storage
 Material

Greater than the sum of its parts:

Hydrogen storage in complex hydrides is accelerated by using the ternary composite $2\text{LiNH}_2/\text{LiBH}_4/\text{MgH}_2$, which exhibits a “self-catalyzing” reaction pathway that results in faster H_2 desorption, lower desorption temperatures, and suppression of NH_3 release in comparison to the constituent binary composites (see diagram). The enhanced properties arise from the incorporation of an ionic liquid phase ($\text{Li}_4\text{BH}_3\text{H}_{10}$) and from ancillary-reaction seeding of a reversible H_2 storage reaction.
